Function Context: A1

Function Background

This function comes from Django ORM's model-checking logic. Django allows developers to configure default ordering fields for database models. The function checks whether a model's ordering configuration is valid and collects any detected issues.

Input and Output

Input: cls, the model class being checked.

Output: A list of errors. An empty list indicates that no issues were found; a non-empty list indicates errors in the ordering configuration.

Key Terms

Term	Meaning
ORM	Object-relational mapping: representing database models using Python classes.
ordering	The model's default ordering-field configuration.
order_with_respect_to	A Django model option related to relative ordering.
_meta	A metadata object that stores information such as model fields and relationships.
pk	The primary-key field.
related field	A field that refers to another model.
lookup	An operation supported by a field for querying.
transform	An operation that transforms a field value before querying.

Helper Variables and Functions

Name	Brief Description
LOOKUP_SEP	The separator used in related-field paths.
_meta.get_field(name)	Looks up a model field by name.
get_lookup(name)	Checks whether a field supports a specified lookup.
get_transform(name)	Checks whether a field supports a specified transform.
path_infos	Describes information about a model relationship path.

Background Not Required

Participants do not need to understand the complete implementation of Django ORM or be familiar with database migrations. They only need to use the function's internal logic to determine how the configuration is checked.
